SKELETAL MUSCLE

Primary Disciplinary Field(s): Anatomy, Physiology, Biomechanics

1. Core Definition and Nomenclature

Skeletal muscle constitutes one of the three major types of muscle found within the human and animal body, alongside cardiac muscle and smooth muscle. Fundamentally, skeletal muscle is the specialized tissue responsible for generating the mechanical force necessary to move the **skeleton**, maintaining posture, and facilitating locomotion. These muscles are characteristically attached to bones, typically via robust connective tissues known as **tendons**, and span across joints, acting as levers to produce movement when they contract. This type of muscle is unique in that its actions are predominantly under **voluntary control** of the somatic nervous system, meaning that conscious thought dictates its activation and force generation.

Due to its distinctive histological appearance, skeletal muscle is often referred to as **striated muscle**. This descriptive term arises from the highly regular, alternating light and dark bands (striations) visible when the tissue is observed under a light microscope. These striations reflect the organized, repeating structure of the contractile units within the muscle fibers, known as sarcomeres. Functionally, skeletal muscle operates in reciprocal pairs--a principle that is central to efficient movement--where the action of one muscle (the agonist) is opposed by the relaxation of another (the antagonist), ensuring controlled and coordinated motion around a joint.

The distinction between skeletal, cardiac, and smooth muscle is vital in physiology. While cardiac muscle is also striated, it is involuntary and possesses unique intercalated discs for coordinated electrical activity; smooth muscle, conversely, is non-striated, involuntary, and typically associated with the walls of internal organs and blood vessels. The defining characteristics of skeletal muscle--its voluntary control, its attachment to the skeleton, and its striated appearance--set it apart as the primary effector of interaction with the external environment.

2. Gross Anatomy and Attachments

At the macroscopic level, skeletal muscle is organized into distinct organs, often referred to simply as "muscles," such as the biceps or the quadriceps femoris. A typical muscle belly is encased in a dense layer of connective tissue called the **epimysium**. This outer layer serves to protect the muscle and provides lubrication against other muscles and surrounding structures. Within the muscle belly, the tissue is further partitioned into bundles of muscle fibers, known as **fascicles**. Each fascicle is surrounded by its own sheath of connective tissue, the **perimysium**, which houses blood vessels and nerves that service the muscle fibers within the bundle.

The individual muscle cells themselves--often called muscle fibers or myocytes--are sheathed by a

ARABPSYCHOLOGY.COM

delicate layer of connective tissue known as the **endomysium**. This intricate, layered arrangement of connective tissues (epimysium, perimysium, and endomysium) is critical because it converges at the ends of the muscle belly to form the extremely tough, fibrous cords known as **tendons**. These tendons are the mechanisms by which the muscle's contractile force is transmitted across joints to the periosteum of the bone, pulling the skeleton and generating movement. The efficiency of force transfer relies entirely on the integrity of this hierarchical structure.

Skeletal muscles function based on their attachments: the **origin**, which is typically the less mobile or proximal attachment point, and the **insertion**, which is the more movable or distal attachment point. When the muscle contracts, the insertion is pulled toward the origin. The arrangement of muscle fibers within the muscle--such as parallel, fusiform, circular, or pennate--directly influences the muscle's potential force generation and range of motion. Pennate muscles, where fibers attach obliquely to a central tendon, generally maximize force due to a larger number of fibers packed into a given volume, whereas parallel muscles maximize the speed and range of shortening.

3. Microscopic Structure (Histology)

The fundamental unit of skeletal muscle is the muscle fiber, which is a highly specialized, elongated, cylindrical cell that can be exceptionally long (sometimes spanning the entire length of the muscle). These cells are **multinucleated**, containing hundreds of nuclei located just beneath the cell membrane, reflecting their embryonic origin as the fusion of numerous myoblasts. The plasma membrane of the muscle fiber is called the **sarcolemma**, which possesses specialized invaginations known as T-tubules (transverse tubules) that plunge deep into the muscle fiber, facilitating the rapid distribution of electrical signals throughout the cell interior.

The cytoplasm within the muscle fiber is termed the **sarcoplasm**. This sarcoplasm is rich in glycogen (for energy storage), myoglobin (for oxygen binding), and mitochondria (for aerobic respiration). Crucially, the sarcoplasm contains the sarcoplasmic reticulum (SR), a specialized form of endoplasmic reticulum that tightly regulates the concentration of intracellular calcium ions ($Ca^{2?}$). Flanking the T-tubules, the terminal cisternae of the SR form a critical structure known as the triad, which is essential for initiating muscle contraction.

The vast majority of the sarcoplasm is occupied by long, cylindrical organelles called **myofibrils**. These myofibrils are the true contractile apparatus of the muscle fiber, and it is the precise, repetitive organization of protein filaments within them that gives skeletal muscle its characteristic striated appearance. Each myofibril is composed of thousands of repeating functional units called **sarcomeres**. The sarcomere is defined as the region between two successive Z-discs (or Z-lines) and contains two primary types of myofilaments: thick filaments composed primarily of **myosin**, and thin filaments composed primarily of **actin**, along with regulatory proteins like troponin and tropomyosin.

4. Functional Classification: Voluntary and Reciprocal Action

A defining characteristic of skeletal muscle is its **voluntary nature**. Unlike the intrinsic rhythmicity of cardiac muscle or the hormonal regulation of smooth muscle, skeletal muscle contraction is initiated primarily by signals originating in the cerebral cortex, traveling down the spinal cord, and synapsing with motor neurons. This voluntary control allows for complex, fine motor movements as well as large, powerful actions, granting the organism mastery over its physical interaction with the environment. Even involuntary reflexes, such as the knee-jerk reflex, utilize the skeletal musculature but bypass the conscious control centers for rapid response.

Skeletal muscles rarely operate in isolation; rather, they function within cooperative groups. The principle of **reciprocal action** dictates that movement at a joint involves carefully balanced forces. A muscle primarily responsible for a specific movement is termed the **agonist** (or prime mover). For instance, the biceps brachii acts as the agonist during forearm flexion. Simultaneously, muscles that oppose or reverse that action are termed **antagonists**; in the case of forearm flexion, the triceps brachii acts as the antagonist. For smooth movement to occur, when the agonist contracts, the antagonist must relax to permit the action.

Beyond agonists and antagonists, movement often involves **synergists** and fixators. Synergists are muscles that aid the agonist, either by adding extra force to the movement or by reducing unwanted movement. Fixators are a specialized type of synergist that stabilize the proximal portion of a limb or joint during movement. For example, when curling a weight, the muscles stabilizing the shoulder joint prevent unwanted rotation, ensuring that the force generated by the biceps is effectively translated to the forearm. This sophisticated coordination, managed subconsciously by the cerebellum and basal ganglia, ensures that movements are efficient, smooth, and precisely controlled.

5. Mechanism of Contraction: The Sliding Filament Theory

The process by which skeletal muscle contracts is best explained by the **Sliding Filament Theory**, which describes how the thick and thin filaments within the sarcomere slide past one another, causing the sarcomere to shorten without the filaments themselves changing length. This complex process is initiated by an electrical impulse from a motor neuron that releases the neurotransmitter acetylcholine (ACh) at the neuromuscular junction. This signal propagates across the sarcolemma and down the T-tubules, triggering a crucial event in muscle excitation-contraction coupling.

The electrical signal reaching the triad stimulates the release of **calcium ions ($Ca^{2?}$)** from the sarcoplasmic reticulum into the sarcoplasm. Calcium is the molecular switch for contraction. In a resting muscle, the regulatory protein tropomyosin blocks the active binding sites on the actin filaments, preventing interaction with myosin. When $Ca^{2?}$ floods the sarcoplasm, it binds to

ARABPSYCHOLOGY.COM

troponin, causing troponin to change shape. This conformational change pulls tropomyosin away from the actin binding sites, exposing them to the myosin heads.

Once the binding sites are exposed, the energized **myosin heads**--which have already hydrolyzed ATP into ADP and inorganic phosphate (Pi)--attach to the actin filament, forming a cross-bridge. The release of ADP and Pi triggers the **power stroke**, where the myosin head pivots and pulls the thin actin filament toward the center of the sarcomere (the M line). Following the power stroke, a new molecule of ATP must bind to the myosin head to cause the detachment of the cross-bridge. This cycle of attachment, pivoting, detachment, and re-energizing continues as long as calcium and ATP are present, resulting in the sequential shortening of all sarcomeres within the myofibril and, consequently, the contraction of the entire muscle fiber.

6. Types of Skeletal Muscle Fibers

Skeletal muscle is not homogeneous; it contains a mixture of different fiber types optimized for varying metabolic demands and functional roles. These fibers are classified primarily based on their speed of contraction and their primary metabolic pathway for ATP generation (oxidative vs. glycolytic). Understanding these differences is essential for recognizing how muscles are adapted for endurance versus explosive power. The three main types are Type I, Type IIa, and Type IIb (or IIx).

Type I fibers, often called slow-oxidative or slow-twitch fibers, contract slowly but are highly resistant to fatigue. They possess a high concentration of mitochondria and myoglobin, giving them a characteristic dark red color (hence the term "red muscle"). These fibers rely heavily on aerobic respiration (oxidative phosphorylation) for continuous ATP production, making them ideal for sustained activities like maintaining posture or long-distance running. Their motor units are typically smaller, allowing for highly precise, low-force contractions.

Conversely, **Type II fibers** are fast-twitch fibers, built for powerful, rapid contraction. These are further subdivided: **Type IIa** (fast oxidative-glycolytic) fibers are intermediate, possessing both high contractile speed and moderate resistance to fatigue due to their utilization of both aerobic and anaerobic pathways. They are often used in moderate-intensity activities. **Type IIb** (fast glycolytic) fibers are true "white muscle." They contract very rapidly and powerfully, but fatigue quickly because they rely almost exclusively on anaerobic glycolysis. They have few mitochondria and little myoglobin, making them suited only for short, explosive movements like sprinting or heavy lifting. The relative proportion of these fiber types varies genetically among individuals and can also be modified to some extent by targeted exercise training.

7. Motor Units and Neuromuscular Control

The functional connection between the nervous system and skeletal muscle is the **motor unit**. A

ARABPSYCHOLOGY.COM

motor unit consists of a single motor neuron (originating in the spinal cord or brainstem) and all the muscle fibers that this neuron innervates. When the motor neuron fires an action potential, all muscle fibers in its motor unit are simultaneously stimulated and contract according to the **all-or-none principle**. The size of the motor unit dictates the precision of control; muscles requiring fine control (e.g., those controlling the eye or fingers) have small motor units (a few fibers per neuron), while large muscles responsible for gross movements (e.g., the quadriceps) have large motor units (hundreds of fibers per neuron).

The site of communication between the axon terminal of the motor neuron and the muscle fiber is the specialized synapse known as the **neuromuscular junction (NMJ)**. This is where the motor neuron releases acetylcholine (ACh) into the synaptic cleft. ACh binds to receptors on the motor end plate of the sarcolemma, triggering depolarization that leads to the action potential that initiates contraction. Effective transmission across the NMJ is crucial for movement; failures here, such as those caused by certain toxins or autoimmune diseases like myasthenia gravis, lead to severe muscle weakness or paralysis.

The force generated by a skeletal muscle is modulated in two primary ways: **recruitment** and **rate coding**. Recruitment involves increasing the number of active motor units; the brain recruits smaller, fatigue-resistant motor units first (Type I) and only engages larger, more powerful, fast-twitch units (Type II) when greater force is required (the Size Principle). Rate coding involves increasing the frequency of stimulation to the active motor units. Higher frequency stimulation leads to the temporal summation of contractile forces, ultimately resulting in tetanus (sustained, maximal contraction), ensuring the muscle can generate a spectrum of forces appropriate for the task at hand.
